1 WTI Crude Oil Futures: Predictive Analysis for Energy Trading Strategies

1.1 Instrument Mechanics · Market Participants · Geopolitical Event Study · Predictive Models

1.2 Target Audience

This analysis is designed for **three practitioner groups**:

1. **Energy Trading Desks** at investment banks and commodity funds — who need quantitative signals to time entries and exits in WTI futures
 2. **Portfolio Managers** running multi-asset funds with crude oil exposure — who need to size positions and manage drawdown risk around macro events
 3. **Corporate Treasury Teams** at oil producers and refiners — who use WTI futures for operational hedging and need to understand when geopolitical events meaningfully shift their hedge costs
-

1.3 Motivation

The global WTI crude oil futures market (NYMEX ticker: CL) represents over **\$2 trillion in daily notional trading volume**. Even a marginal improvement in price-direction prediction translates into measurable alpha. More importantly, the structural shift in US energy production since the shale revolution (~2008–2014) is widely claimed to have *reduced* the geopolitical risk premium embedded in oil prices. This analysis tests that claim rigorously across five decades of crisis events.

Two datasets are used: - **FRED API** — daily WTI spot prices (DCOILWTIC0), updated daily, sourced from the US Energy Information Administration - **CFTC Commitments of Traders** — weekly disaggregated positioning data for WTI futures, providing a second independent dataset on market participant behaviour

1.4 Research Questions

1. **Predictability** — How well can **3-day ahead WTI price levels** and **3-day strong-up direction** be predicted from technical indicators?

2. **Geopolitical risk premium** — Has US energy independence structurally reduced WTI's response to geopolitical shocks?
3. **Participant behaviour** — Do commercial hedgers and speculative funds position differently ahead of and after crisis events?
4. **Signal utility** — Do momentum, volatility, and positioning features add predictive power beyond simple price autocorrelation?

Data Sources: FRED API (daily) · CFTC COT Reports (weekly)

Analysis Date: Updated automatically to current date

1.4.1 Method Scope, Reproducibility, and Practical Conventions

- **As-of-date behavior:** This notebook pulls the latest available data at runtime, so exact numerical outputs can vary by run date.
- **Trading-calendar handling:** Non-trading-day events are matched to the nearest available WTI trading date.
- **Frequency mismatch handling:** WTI is daily while COT is weekly; participant interpretation uses the closest prior available COT report.
- **Proxy convention:** WTI spot (DCOILWTIC0) is used as an observable proxy for front-month futures dynamics in explanatory sections.
- **Interpretation standard:** Positioning and event-study results are explanatory associations, not strict causal claims.

2 SETUP: Install Packages & Import Libraries

```
[1]: # Install ALL required packages
!pip install fredapi requests pandas numpy matplotlib seaborn cot-reports -q

print(" All packages installed")
```

All packages installed

2.1 Part 1: Instrument Mechanics

2.1.1 Defining the Tool

A WTI crude oil futures contract (CL) is a standardised agreement to **buy or sell 1,000 barrels of West Texas Intermediate crude oil** at a fixed price on a future delivery date. The contract

trades on NYMEX (CME Group) and settles with physical delivery at Cushing, Oklahoma — the pricing hub for US crude.

Why this instrument matters to our target audience: - Trading desks use CL to express directional views on oil prices with leverage - Portfolio managers use it as a liquid proxy for broad energy exposure - Corporate hedgers use it to lock in future sale or purchase prices, eliminating price uncertainty from operating budgets

The analysis below uses **real-time FRED API data** to anchor all payoff calculations to actual recent market prices.

```
[4]: # Fetch LATEST WTI prices (most recent 90 days)
print("Fetching latest WTI price data from FRED...\n")

end_date = datetime.now().strftime('%Y-%m-%d')
start_date = (datetime.now() - timedelta(days=90)).strftime('%Y-%m-%d')

try:
    wti_prices = fred.get_series('DCOILWTICO',
                                observation_start=start_date,
                                observation_end=end_date)
    wti_prices = wti_prices.dropna()

    print(f"  Fetched {len(wti_prices)} WTI price observations")
    print(f"  Date range: {wti_prices.index[0].strftime('%Y-%m-%d')} to {wti_prices.index[-1].strftime('%Y-%m-%d')}")

except Exception as e:
    print(f"  Error fetching FRED data: {e}")
    raise

2.2 WTI Contract Specifications

Specification	Details
Ticker	CL

Specification	Details
Exchange	NYMEX (CME Group)
Contract Size	1,000 barrels
Delivery	Physical at Cushing, Oklahoma
Tick Size	\$0.01/barrel = \$10/contract

2.3 Payoff Mathematics

Long Position: $P\&L = (S_T - F_0) \times 1,000$

Short Position: $P\&L = (F_0 - S_T) \times 1,000$

Zero-Sum Property: Long P&L + Short P&L = 0

```
[6]: # Define payoff functions
def futures_payoff_long(spot_price, futures_price, contract_size=1000):
    """Calculate P&L for LONG futures position."""
    return (spot_price - futures_price) * contract_size

def futures_payoff_short(spot_price, futures_price, contract_size=1000):
    """Calculate P&L for SHORT futures position."""
    return (futures_price - spot_price) * contract_size

print(" Payoff functions defined")
```

Payoff functions defined

2.3.1 Payoff Diagram — Using Real Price Data

The chart below shows the P&L profile for long and short WTI futures positions, anchored to the **most recent week's actual price move**. The green dot marks the long position's realised P&L; the red dot marks the short position's realised P&L.

Interpretation: The zero-sum nature of futures is visually confirmed — whatever the long makes, the short loses by exactly the same amount per contract.

```
[7]: # Generate payoff diagram using REAL price data
price_range = np.linspace(PRICE_ENTRY - 20, PRICE_EXIT + 20, 100)

long_payoffs = futures_payoff_long(price_range, PRICE_ENTRY)
short_payoffs = futures_payoff_short(price_range, PRICE_ENTRY)

# Calculate actual P&L at current exit price
pnl_long = futures_payoff_long(PRICE_EXIT, PRICE_ENTRY)
pnl_short = futures_payoff_short(PRICE_EXIT, PRICE_ENTRY)

# Visualize
fig, ax = plt.subplots(figsize=(14, 8))

ax.plot(price_range, long_payoffs/1000, linewidth=3,
```

```

        label='Long Position', color='#2E7D32')
ax.plot(price_range, short_payoffs/1000, linewidth=3,
        label='Short Position', color='#C62828')

# Reference lines
ax.axhline(y=0, color='black', linestyle='--', linewidth=1.5, alpha=0.5)
ax.axvline(x=PRICE_ENTRY, color='blue', linestyle='--', linewidth=2, alpha=0.7,
          label=f'Entry: ${PRICE_ENTRY:.2f} ({date_before.strftime("%b %d")})')
ax.axvline(x=PRICE_EXIT, color='purple', linestyle='--', linewidth=2, alpha=0.7,
          label=f'Exit: ${PRICE_EXIT:.2f} ({latest_date.strftime("%b %d")})')

# Highlight actual outcomes
ax.plot(PRICE_EXIT, pnl_long/1000, 'o', markersize=15, color='green',
        label=f'Long P&L: ${pnl_long/1000:+,.1f}k', zorder=5)
ax.plot(PRICE_EXIT, pnl_short/1000, 'o', markersize=15, color='red',
        label=f'Short P&L: ${pnl_short/1000:+,.1f}k', zorder=5)

# Profit/loss zones
ax.fill_between(price_range, 0, long_payoffs/1000,
               where=(price_range >= PRICE_ENTRY),
               alpha=0.2, color='green', label='Long Profit Zone')
ax.fill_between(price_range, 0, long_payoffs/1000,
               where=(price_range < PRICE_ENTRY),
               alpha=0.2, color='red', label='Long Loss Zone')

ax.set_xlabel('WTI Spot Price at Settlement ($/barrel)', fontsize=12,
             fontweight='bold')
ax.set_ylabel('Profit/Loss per Contract ($1,000s)', fontsize=12,
             fontweight='bold')
ax.set_title(f'WTI Futures Payoff Diagram\n' +
            f'REAL Market Data: ${PRICE_ENTRY:.2f} → ${PRICE_EXIT:.2f}\n'
            f'({PRICE_CHANGE:+.2f}, {PERCENT_CHANGE:+.1f}%)',
            fontsize=14, fontweight='bold', pad=15)
ax.legend(loc='upper left', fontsize=10, framealpha=0.95)
ax.grid(True, alpha=0.3)

plt.tight_layout()
plt.show()

print(f"\nZero-Sum Verification: ${pnl_long + pnl_short:+.0f} (should be $0)")

```

Zero-Sum Verification: \$0 (should be \$0)

Interpretation: Payoff Diagram What this chart tells us (current run): - WTI futures P&L is linear: each \$1/bbl move = \$1,000 per contract. - The realised one-week move from Part 1 directly maps into equal-and-opposite long/short outcomes.

Why this matters for the target audience: 1. **Energy Trading Desks:** position size can be back-solved from acceptable weekly P&L variance (contracts = risk budget / \$1,000-per-\$1 move). 2. **Portfolio Managers:** this is the translation layer from price view to mark-to-market impact, needed for cross-asset risk aggregation. 3. **Corporate Treasury / Hedgers:** hedge ratio decisions can be expressed in contract counts with transparent downside/upside payoff trade-offs.

Actionable rule-of-thumb: - Before entering any view, convert expected move and adverse move into contract-level P&L first; then decide leverage and stop-loss/hedge overlay.

2.4 Part 2: Market Participants

2.4.1 Who Trades WTI Futures and Why?

The CFTC's weekly **Commitments of Traders (COT)** report disaggregates open interest into three categories:

Participant	Motive	Typical Position
Commercial Hedgers (producers/refiners)	Lock in future revenues or input costs	Net short (producers selling forward)

Participant	Motive	Typical Position
Managed Money (hedge funds, CTAs)	Speculative profit	Net long in bull markets, net short in bear markets
Swap Dealers (banks)	Intermediation and balance-sheet risk mgmt	Variable, often opposite to managed money

Why this matters: When managed money is extremely net long, contrarian signals tend to be more reliable. When commercial hedgers rapidly increase short positions, it often signals they expect lower prices — a bearish fundamental signal.

The second dataset (CFTC COT) provides an independent view of market structure that complements the FRED price series.

2.4.2 Part 2 Interpretation Framework

- Net positioning captures aggregate risk stance by participant class.
- The “positioning $\times$ weekly price move” P&L table is a **didactic approximation** for intuition, not a full contract-level attribution model.
- Main use in this project: identify which participant cohorts are directionally aligned or crowded before observed market moves.

2.4.3 CFTC Positioning — Latest 18 Months

The chart below shows net positions (long minus short, in thousands of contracts) for each participant category over the most recent 18 months. The purple dashed line marks our analysis week.

Interpretation: Divergence between commercial (red) and managed money (green) lines is a classic contrarian signal. When the spread is at an extreme, prices often reverse.

```

[10]: if USE_COT_LIBRARY:
        # Plot latest 18 months of REAL data
        cutoff = cot_processed['Date'].max() - pd.DateOffset(months=18)
        recent_data = cot_processed[cot_processed['Date'] >= cutoff].copy()

        fig, ax = plt.subplots(figsize=(16, 8))

```

```

ax.plot(recent_data['Date'], recent_data['Commercial_Net']/1000,
        linewidth=2.5, label='Commercial (Hedgers)', color='#d62728',
        marker='o', markersize=3)
ax.plot(recent_data['Date'], recent_data['Managed_Money_Net']/1000,
        linewidth=2.5, label='Managed Money (Speculators)',
↪color='#2ca02c',
        marker='s', markersize=3)
ax.plot(recent_data['Date'], recent_data['Swap_Dealer_Net']/1000,
        linewidth=2, label='Swap Dealers (Banks)', color='#ff7f0e',
        marker='^', markersize=3, alpha=0.7)

ax.axhline(y=0, color='black', linestyle='--', linewidth=1.5, alpha=0.5)
ax.fill_between(recent_data['Date'], 0, recent_data['Commercial_Net']/1000,
               alpha=0.15, color='red')
ax.fill_between(recent_data['Date'], 0, recent_data['Managed_Money_Net']/
↪1000,
               alpha=0.15, color='green')

# Highlight analysis week
analysis_date = pd.to_datetime(date_before)
if analysis_date >= recent_data['Date'].min():
    ax.axvline(x=analysis_date, color='purple', linestyle='--',
               linewidth=2.5, alpha=0.7,
               label=f'Analysis Week: {date_before.strftime("%Y-%m-%d")}')

ax.set_ylabel('Net Position (Thousands of Contracts)', fontsize=12,
↪fontweight='bold')
ax.set_xlabel('Date', fontsize=12, fontweight='bold')
ax.set_title('WTI Futures: LATEST Market Positioning (18 Months)\n' +
             f'From Real CFTC Data - Updated {cot_processed["Date"].max()}.
↪strftime("%Y-%m-%d")}',
             fontsize=14, fontweight='bold', pad=15)
ax.legend(loc='upper left', fontsize=10)
ax.grid(True, alpha=0.3)

plt.tight_layout()
plt.show()

else:
    print("\n Skipping positioning chart (CFTC data not available)")

```

Interpretation: CFTC Positioning Chart What this chart tells us: - Participant cohorts carry structurally different risk roles: Commercials (hedging), Managed Money (speculation), Swap Dealers (intermediation). - When **Managed Money and Commercial net positioning diverge sharply**, crowding and reversal risk usually increase.

Why this matters for the target audience: 1. **Trading Desks:** large speculative net-long crowds can justify tighter risk limits or contrarian overlays. 2. **Portfolio Managers:** positioning divergence is a regime indicator for drawdown risk, especially around event windows. 3. **Corporate Hedgers:** extreme speculative positioning can distort short-term hedge-entry levels; staggered hedge execution becomes more valuable.

Actionable use in this project: - Treat extreme net-position divergence as a risk-state flag, then combine with event timing (Part 3) and model signals (Part 4) before sizing.

2.4.4 Market P&L Analysis — Latest Positioning

Using the most recent CFTC report and the actual weekly price change from Part 1, we calculate the estimated P&L for each participant group.

Note: These are approximate aggregate P&L figures assuming each group's net position is fully exposed to the weekly price move. In practice, delta-hedging and portfolio effects reduce actual P&L sensitivity.

```
[11]: if USE_COT_LIBRARY:

2.5 Part 3: Historical Event Study

2.5.1 Comparing WTI's Response to 5 Major Geopolitical Crises (1990–2026)

Research Question 2: Has US Energy Independence Reduced the Geopolitical Risk Premium? This section tests the central thesis of the analysis: that WTI's sensitivity to geopolitical shocks has **structurally declined** as US domestic oil production rose from ~5 mb/d in 2008 to ~13 mb/d by 2024, making the US the world's largest producer.

We compare five events across three US energy eras:

Era	Years	US Production Context
US Dependent	1990–2004	US imports ~60% of consumption; high geopolitical sensitivity
Transition	2005–2013	Shale revolution begins; sensitivity starts declining
US Independent	2014–2018	US approaches self-sufficiency
US Dominant	2019–present	US is world’s largest producer; geopolitical risk premium compressed

Methodology: For each event, we fetch WTI prices from FRED covering 60 days before to 180 days after the event date. We normalise prices to 1.0 at the event date, allowing direct comparison of proportional responses across different price levels.

2.5.2 Event-Study Design Notes

- Event list is thesis-driven and kept consistent with the original narrative.
- Prices are normalized to day 0 so cross-era shock shapes are directly comparable.
- Metrics (peak move, 30/90-day drift, early volatility) are designed for decision relevance, not for causal inference.
- Era labels provide a structured lens for discussing how shock transmission may have changed over time.

2.6 Define Historical Events

```
[12]: # Determine the 5th event date using LATEST available data
print("Checking latest available data for 5th event...\n")

FRED_LATEST_DATE = wti_prices.index[-1]
print(f" FRED latest date: {FRED_LATEST_DATE.strftime('%Y-%m-%d')}")
print(f" Latest price: ${wti_prices.iloc[-1]:.2f}/barrel")

# Use a date from the recent past as the 5th event
# (typically 1-4 weeks before latest to have some post-event data)
EVENT_5_DATE = (FRED_LATEST_DATE - timedelta(days=7)).strftime('%Y-%m-%d')
EVENT_5_NAME = f"{FRED_LATEST_DATE.year} Latest Event"

print(f"\n Using {EVENT_5_DATE} as 5th event (most recent with data)")
print("="*80)
```

Checking latest available data for 5th event...

```

2.8.1 Event Response Metrics

The table below summarises the quantitative impact of each crisis on WTI prices. Key metrics: - **Peak 30d %** — maximum price increase in the 30 days after the event (measures initial shock) - **30d Change** — price 30 days after vs. event price (measures short-run persistence) - **90d Change** — price 90 days after vs. event price (measures medium-run persistence) - **Volatility** — annualised realised volatility in the 30-day post-event window

```
[16]: metrics = []

2.8.3 Visualisation 1: Normalised Price Overlay

Each line shows WTI price normalised to 1.0 at the event date. The shaded regions mark the pre-event (yellow), immediate post-event (orange, 0–30 days), and extended (blue, 30–180 days) windows.

What to look for: The height of the peak in the orange zone, and whether prices revert toward 1.0 in the blue zone.

```

[18]: fig, ax = plt.subplots(figsize=(18, 11))

# Plot each event
for key, data in event_data.items():
    event = events[key]

    days = data['days_from_event']
    normalized = data['normalized']

    mask = (days >= -event['window_before']) & (days <= event['window_after'])
    x_data = days[mask]
    y_data = normalized[mask]

```

```

# Plot with emphasis on recent events
ax.plot(x_data, y_data,

print("\n KEY INSIGHT: Recent events show MUCH flatter response vs 1990-2011")
```

KEY INSIGHT: Recent events show MUCH flatter response vs 1990-2011

Interpretation: Event Overlay Chart What this chart tells us: - Normalized overlays compare **shock shape** (spike, persistence, mean reversion) across eras on a common baseline. - Older dependent-era events show larger and/or more persistent disruptions than more recent dominant-era events.

Why this matters for the target audience: 1. **Trading Desks:** event-premium trades should be horizon-specific; recent-era spikes often normalize faster than legacy crisis templates suggest. 2. **Portfolio Managers:** stress scenarios should not assume every geopolitical event behaves like 1990-style oil shocks. 3. **Corporate Hedgers:** hedge tenor should align with expected persistence, not only immediate spike size.

Actionable implication: - Use era-conditioned scenarios when setting event risk limits; avoid applying a single crisis response template to all events.

2.8.4 Visualisation 2: Peak Price Response by Event

This chart directly compares the maximum price increase (within the first 30 days) across all five events, ordered chronologically.

Key finding from the data: Peak price response has declined substantially over time — from double-digit spikes in the US Dependent era to single-digit moves in the US Dominant era — consistent with the hypothesis that US energy independence has compressed the geopolitical risk premium.

```
[19]: # Extract peak change data for each event
peak_data = []
for key, data in event_data.items():
    event = events[key]
    event_idx = data['prices'].index.get_loc(data['event_date'])
    window_30d = data['prices'].iloc[event_idx:min(event_idx+30,
    ↪len(data['prices']))]

    if len(window_30d) > 0:
        peak_pct = ((float(window_30d.max()) - data['event_price']) /
    ↪data['event_price']) * 100
    else:
        peak_pct = 0

    row = {
        'Event': event['name'],
        'Year': int(event['event_date'][:4]),
        'Era': event['era'],
        'Peak_Change': peak_pct,
        'Color': event['color']
    }

    # Add CFTC data if available
    if data.get('managed_money_net') is not None:
        row['MM_Net'] = data['managed_money_net']

    peak_data.append(row)

df_peak = pd.DataFrame(peak_data).sort_values('Year')

# Create chart (dual-axis if CFTC available)
fig, ax1 = plt.subplots(figsize=(16, 9))

x_pos = range(len(df_peak))
bars = ax1.bar(x_pos, df_peak['Peak_Change'],
               color=df_peak['Color'], edgecolor='black',
               linewidth=2, alpha=0.85, width=0.6)

# Value labels
for i, (bar, val) in enumerate(zip(bars, df_peak['Peak_Change'])):
    ax1.text(bar.get_x() + bar.get_width()/2, bar.get_height() + 1.5,
             f'{val:.1f}%',
```

```

        ha='center', va='bottom', fontsize=13, fontweight='bold')

ax1.set_xticks(x_pos)
ax1.set_xticklabels([f"{row['Event']}\n({row['Year']})"
                    for _, row in df_peak.iterrows()],
                    fontsize=12, fontweight='bold')
ax1.set_ylabel('Peak Price Increase (First 30 Days, %)',
               fontsize=14, fontweight='bold', color='darkblue')
ax1.tick_params(axis='y', labelcolor='darkblue')
ax1.grid(True, alpha=0.3, axis='y', linestyle=':')
ax1.axhline(y=0, color='black', linewidth=1.5)

# Add CFTC overlay if available
if 'MM_Net' in df_peak.columns:
    ax2 = ax1.twinx()
    ax2.plot(x_pos, df_peak['MM_Net']/1000, 'o-', color='darkgreen',
             linewidth=2.5, markersize=10, label='Speculator Position')
    ax2.set_ylabel('Managed Money Net (Thousands)',
                  fontsize=12, fontweight='bold', color='darkgreen')
    ax2.tick_params(axis='y', labelcolor='darkgreen')

    title_suffix = '\nwith Market Positioning Context'
else:
    title_suffix = ''

ax1.set_title('Peak WTI Price Response: Evolution Across Decades' + title_suffix +
             '\n' +
             'US Energy Independence Reduces Volatility',
             fontsize=16, fontweight='bold', pad=20)

plt.tight_layout()
plt.show()

print(f"\n Peak response: {df_peak['Peak_Change'].iloc[0]:.0f}% (1990) →
      {df_peak['Peak_Change'].iloc[-1]:.0f}% (recent)")

```

Peak response: 34% (1990) → 7% (recent)

Interpretation: Peak Response Comparison What this chart tells us: - Peak 30-day jump magnitude differs materially by event and era, revealing asymmetric event intensity. - The bar ranking helps separate **headline risk** from **actual realized price shock**.

Why this matters for the target audience: 1. **Trading Desks:** supports event-day position caps and take-profit rules based on expected peak range. 2. **Portfolio Managers:** informs scenario-based VaR stress levels by event class rather than one-size-fits-all shocks. 3. **Corporate Hedgers:** indicates when immediate hedge acceleration is justified versus when gradual layering is sufficient.

Actionable implication: - Use peak-response buckets (high/medium/muted) to pre-define event playbooks for sizing and hedge urgency.

2.8.5 Visualisation 3: Post-Event Volatility by Crisis

This chart shows the annualised realised volatility of WTI in the 30 days following each event.

Key finding: Post-event volatility shows a broadly declining trend across eras, though it is not monotonic (individual events vary by their specific supply disruption severity). This supports the conclusion that WTI markets have become structurally more stable in the US Dominant era.

```
[20]: # Calculate volatility for each event
vol_data = []
for key, data in event_data.items():
    event = events[key]
    event_idx = data['prices'].index.get_loc(data['event_date'])
```

```

# 30-day window after event
window = data['prices'].iloc[event_idx:min(event_idx+30,
len(data['prices']))]
if len(window) > 1:
    returns = window.pct_change().dropna()
    vol = float(returns.std() * np.sqrt(252) * 100) # Annualized
else:
    vol = 0

vol_data.append({
    'Event': event['name'],
    'Year': int(event['event_date'][:4]),
    'Era': event['era'],
    'Volatility': vol,
    'Color': event['color']
})

df_vol = pd.DataFrame(vol_data).sort_values('Year')

fig, ax = plt.subplots(figsize=(16, 9))

bars = ax.bar(range(len(df_vol)), df_vol['Volatility'],
              color=df_vol['Color'], edgecolor='black',
              linewidth=2, alpha=0.85, width=0.6)

# Value labels
for i, (bar, val) in enumerate(zip(bars, df_vol['Volatility'])):
    ax.text(bar.get_x() + bar.get_width()/2, bar.get_height() + 1.5,
            f'{val:.1f}%',
            ha='center', va='bottom', fontsize=13, fontweight='bold')

ax.set_xticks(range(len(df_vol)))
ax.set_xticklabels([f"{row['Event']}\n({row['Year']})"
                    for _, row in df_vol.iterrows()],
                    fontsize=12, fontweight='bold')

ax.set_ylabel('Annualized Volatility (First 30 Days, %)',
              fontsize=14, fontweight='bold')
ax.set_title('WTI Price Volatility Following Geopolitical Crises\n' +
            'Market Stability Increases with US Energy Dominance',
            fontsize=16, fontweight='bold', pad=20)

ax.grid(True, alpha=0.3, axis='y', linestyle=':')

# Add trend line
if len(df_vol) >= 3:

```

```

z = np.polyfit(range(len(df_vol)), df_vol['Volatility'], 1)
p = np.poly1d(z)
ax.plot(range(len(df_vol)), p(range(len(df_vol))),
        "--", color='red', linewidth=2, alpha=0.7,
        label=f'Trend: {z[0]:.1f}% decline per event')
ax.legend(fontsize=11)

plt.tight_layout()
plt.show()

print(f"\n Volatility: {df_vol['Volatility'].iloc[0]:.1f}% (1990) →
↪{df_vol['Volatility'].iloc[-1]:.1f}% (recent)")
print("    Systematic reduction in market instability")

```

Volatility: 93.1% (1990) → 49.1% (recent)

Systematic reduction in market instability

Interpretation: Post-Event Volatility Chart What this chart tells us: - Post-event realized volatility is not constant across crises; some episodes stay disorderly longer than others. - Volatility dynamics are a direct risk-management input, not just a descriptive statistic.

Why this matters for the target audience: 1. **Trading Desks:** leverage should be scaled to expected post-event volatility regime. 2. **Portfolio Managers:** volatility persistence determines risk-budget draw speed and rebalance timing. 3. **Corporate Hedgers:** higher post-event vol justifies earlier or larger hedge locking to reduce budget uncertainty.

Actionable implication: - Calibrate position/hedge sizing to expected volatility state after the

event, not only to directional view.

2.10 Part 4: SQL Analysis & Predictive Models

This section adds five components:

1. **Data quality checks** — coverage, missingness, duplicate-date control, and outlier diagnostics
2. **Feature engineering** using `map` and `apply` — building the modelling dataset from event price windows
3. **SQL analysis** via SQLite — 12 queries covering GROUP BYs, window functions, JOINS, and subqueries
4. **Model 1: Linear Regression** — predict **3-day ahead WTI price level**
5. **Model 2: Logistic Regression** — predict **3-day strong-up move** (`future_ret_3d > +0.8%`)

All SQL and model results are interpreted for the target audience and integrated into the conclusions.

2.10.1 Why Part 4 Is Added (Without Changing the Core Story)

Part 4 keeps the same research storyline but adds required final deliverables: - Pandas `map` / `apply` feature engineering, - rubric-compliant SQL complexity (JOIN, window, GROUP BY, subquery), - two predictive models with explicit metrics, - temporal split rules for practical no-look-ahead evaluation.

2.11 Data Preparation: Feature Engineering with `map` and `apply`

We combine the five historical event windows already fetched in Part 3 into a single long-history DataFrame, then engineer features using `map` and `apply`.

```
[22]: import sqlite3
from sklearn.model_selection import train_test_split
from sklearn.linear_model import LinearRegression, LogisticRegression
from sklearn.preprocessing import StandardScaler
from sklearn.metrics import (
    r2_score, mean_squared_error, mean_absolute_error,
    accuracy_score, precision_score, recall_score,
    confusion_matrix, classification_report, roc_auc_score, roc_curve
)

# Combine all event price windows into one long-history DataFrame
all_frames = []
for key, data in event_data.items():
    tmp = data['prices'].copy().to_frame(name='price')
    tmp['era'] = data['era']
    all_frames.append(tmp)

df_long = pd.concat(all_frames)
df_long = df_long[~df_long.index.duplicated(keep='first')].sort_index()
df_long = df_long.reset_index().rename(columns={'index': 'date'})
df_long['date_str'] = df_long['date'].dt.strftime('%Y-%m-%d')
df_long['year'] = df_long['date'].dt.year
df_long['month'] = df_long['date'].dt.month

# Returns and technical indicators
df_long = df_long.sort_values('date').reset_index(drop=True)
df_long['return_1d'] = df_long['price'].pct_change()
df_long['log_ret'] = np.log(df_long['price'] / df_long['price'].shift(1))
df_long['ma_20'] = df_long['price'].rolling(20).mean()
df_long['ma_50'] = df_long['price'].rolling(50).mean()
df_long['volatility_20d'] = df_long['log_ret'].rolling(20).std() * np.sqrt(252)
df_long['momentum_5d'] = df_long['price'] - df_long['price'].rolling(5).
    ↪mean()
```

```

df_long['price_to_ma20'] = df_long['price'] / df_long['ma_20']
df_long['ma_gap']       = (df_long['ma_20'] / df_long['ma_50']) - 1

# map: assign US energy era label by year
era_map = {y: ('US Dependent' if y < 2005 else

```

2.12 Data Quality Checks

This section performs required quality controls before SQL and modeling:

1. **Coverage and integrity checks** across source tables and `df_long`
2. **Missing-value audit** on model-critical fields
3. **Duplicate-date checks** and monotonic date validation
4. **Outlier diagnostics + 1%/99% winsorized helper columns**
5. **Annual coverage sanity table (groupby)** to verify stable regime representation

Why this matters for the target audience: - Trading desks need signals that are not artifacts of missing or duplicated timestamps. - Portfolio/risk teams need volatility metrics that are robust to extreme one-day spikes. - Hedging teams need a transparent data lineage from raw tables to model inputs.

```

[23]: # -- Data Quality Checks -----
# 1) Dataset coverage summary (rows, date range, duplicate-date count)

2.12.1 Exploratory Data Analysis: Aggregate Tables & Pandas GroupBys

Before running SQL queries, we perform three Pandas groupby aggregations directly on `df_long` — the combined long-history price DataFrame built from all five event windows.

```
[24]: # EDA Table 1: Summary statistics by US energy era (Pandas groupby 1)
# Grouped aggregate of price level, volatility, and direction by energy era.
# This tests Research Question 2 at the aggregate level before the event study.
era_summary = (
    df_long.groupby('era_label')
    .agg(
        observations      = ('price',      'count'),
        avg_price          = ('price',      'mean'),
        median_price       = ('price',      'median'),
        price_std          = ('price',      'std'),
        avg_vol_pct        = ('volatility_20d', lambda x: x.mean() * 100),
        pct_positive_days  = ('price_up',    lambda x: x.dropna().mean() * 100),
        avg_daily_ret_pct  = ('return_1d',   lambda x: x.mean() * 100),
    )
    .round(3)
)
era_order = ['US Dependent', 'Transition', 'US Independent', 'US Dominant']
era_summary = era_summary.reindex([e for e in era_order if e in era_summary.index])
print("=== EDA Table 1: WTI Statistics by US Energy Era ===")
print(era_summary.to_string())
```

```

Interpretation: Distribution + Seasonality EDA Charts What these charts tell us:

- Return distributions differ by era (dispersion/tails), implying regime-dependent risk.
- Monthly average volatility shows seasonal unevenness, supporting calendar-aware risk planning.

Why this matters for the target audience:

1. **Trading Desks:** expected payoff dispersion and stop distance should differ by regime and season.
2. **Portfolio Managers:** monthly/era variation helps schedule risk intake and reduce unintended concentration.
3. **Corporate Hedgers:** seasonal volatility windows can guide when to pre-hedge versus wait for better execution windows.

Actionable implication: - Combine regime label + month as practical overlays for leverage, stop placement, and hedge cadence.

2.13 SQL Setup: Load Data into SQLite

We load the combined long-history DataFrame plus the event metrics table into an in-memory SQLite database.

```
[29]: # Load into SQLite
conn = sqlite3.connect(':memory:')

df_long.to_sql('wti_prices', conn, if_exists='replace', index=False)

# Event metrics from Part 3
df_m = df_metrics.copy()
df_m.columns = [c.replace(' ', '_').replace('%', 'pct').replace('/', '_') for c in df_m.columns]
df_m.to_sql('event_metrics', conn, if_exists='replace', index=False)

# Recent 90-day series from Part 1
df_rec = wti_prices.copy().to_frame(name='price').reset_index()
df_rec.columns = ['date', 'price']
df_rec['date_str'] = df_rec['date'].dt.strftime('%Y-%m-%d')
```

```

df_rec['year'] = df_rec['date'].dt.year
df_rec['month'] = df_rec['date'].dt.month
df_rec.to_sql('wti_recent', conn, if_exists='replace', index=False)

print("=== SQLite database loaded ===")
print(f" wti_prices: {pd.read_sql('SELECT COUNT(*) AS n FROM wti_prices',
    ↪conn).iloc[0,0]:,} rows")
print(f" event_metrics:{pd.read_sql('SELECT COUNT(*) AS n FROM event_metrics',
    ↪conn).iloc[0,0]} rows")
print(f" wti_recent: {pd.read_sql('SELECT COUNT(*) AS n FROM wti_recent',
    ↪conn).iloc[0,0]} rows")

```

```

=== SQLite database loaded ===
 wti_prices:    1,271 rows
 event_metrics:5 rows
 wti_recent:    57 rows

```

2.13.1 SQL Queries (12 total)

All queries run on an in-memory SQLite database populated from the FRED and CFTC data fetched in Parts 1–3. Each query includes comments explaining **what it does, how it works, and why it is analytically relevant**.

A standalone, submission-ready version of the same queries is also provided in `WTI_SQL_Queries_FINAL.sql`.

2.13.2 How SQL Findings Connect to the Narrative

- **Q1-Q4:** structural context and event-proximity behavior (quality + regime baseline)
- **Q5-Q6:** rolling/time-rank structure via window functions
- **Q7-Q9:** join-based integration between event summaries and market state
- **Q10-Q12:** extreme-condition filtering via subqueries

These queries are the SQL evidence layer supporting Parts 2-3 conclusions.

```

[30]: # SQL Q1: Annual price and volatility summary - GROUP BY year
# What: Year-over-year average price, price range, and realised volatility.
# How: GROUP BY year with AVG, MIN, MAX aggregations.
# Why: Establishes the macro price regime context for the five event periods.

2.14 SQL Findings for the Target Audience

The SQL outputs provide actionable implications for each audience segment:

1. **Energy Trading Desks:** Q5/Q6/Q9 show when WTI is stretched relative to rolling trends and historical rank, helping define tactical entry/exit zones.
2. **Portfolio Managers:** Q3/Q4/Q11 show volatility-regime concentration by era and event proximity, supporting risk-budget adjustments in crisis windows.
3. **Corporate Treasury / Hedgers:** Q7/Q8 quantify post-event persistence and event-date risk context, helping set hedge-tenor and hedge-ratio timing.
4. **Cross-check with Part 3 narrative:** Q3/Q4 and event-study results consistently support lower average geopolitical sensitivity in the US-dominant era versus earlier eras.

2.15 Predictive Models

2.15.1 Target Variables, Operational Meaning, and Temporal Split Rules

Model 1 target (level forecasting): - future_price_3d: WTI price 3 trading days ahead. - Practical use: short-horizon mark-to-market planning and scenario anchoring.

Model 2 target (direction classification): - price_up_3d = 1{future_ret_3d > 0.8%}. - Practical use: tactical “strong-up” signal for positioning and hedge timing.

Temporal split rule (no look-ahead): - Chronological **80/20 Train/Test** split, no shuffling. - Features at time t are used to predict outcomes at $t+3$ only. - Classification threshold is fixed at 0.48 for reporting consistency in this notebook.

```
[42]: # Feature selection and temporal train/test split (3-day horizon)
# New targets: 3-day ahead price level + 3-day bullish move classifier
df_long['future_price_3d'] = df_long['price'].shift(-3)
df_long['future_ret_3d'] = (df_long['future_price_3d'] / df_long['price']) - 1
df_long['price_up_3d'] = (df_long['future_ret_3d'] > 0.008).astype('Int64')

linear_feature_cols = [

2.15.2 Model 1: Linear Regression — 3-Day Ahead WTI Price Prediction

Instead of predicting the next day (which is dominated by short autocorrelation), this model predicts the **3-day ahead WTI level**. This keeps the original regression requirement while making the task less trivial and more relevant for short holding-period trading decisions.

```
[43]: # Model 1: Linear Regression (3-day ahead price)
model1 = LinearRegression()
model1.fit(X1_train_sc, y1_train)
y_pred1 = model1.predict(X1_test_sc)

r2 = r2_score(y1_test, y_pred1)
rmse = np.sqrt(mean_squared_error(y1_test, y_pred1))
mae = mean_absolute_error(y1_test, y_pred1)
baseline_mae = float((y1_test - y1_test.mean()).abs().mean())

print("=" * 65)
print("MODEL 1: Linear Regression - 3-Day Ahead WTI Price")
print("=" * 65)
print(f" R2 Score : {r2:.4f} (% variance explained)")
print(f" RMSE : ${rmse:.2f} / barrel")
print(f" MAE : ${mae:.2f} / barrel")
print(f" Naive MAE : ${baseline_mae:.2f} (predict-the-mean baseline)")
print("=" * 65)

coef_df = pd.DataFrame({
    'feature': linear_feature_cols,
    'coefficient': model1.coef_
}).sort_values('coefficient', key=abs, ascending=False)
print("\nStandardised Coefficients (most influential features first):")
print(coef_df.to_string(index=False))

# Chart: Actual vs Predicted + Residuals
fig, axes = plt.subplots(1, 2, figsize=(14, 5))

ax1 = axes[0]
ax1.scatter(y1_test, y_pred1, alpha=0.3, s=10, color='steelblue')
lims = [min(float(y1_test.min()), float(y_pred1.min())),
        max(float(y1_test.max()), float(y_pred1.max()))]
ax1.plot(lims, lims, 'r--', lw=2, label='Perfect prediction (y=x)')
ax1.set_xlabel('Actual 3-Day Ahead Price ($/barrel)', fontsize=11)
ax1.set_ylabel('Predicted Price ($/barrel)', fontsize=11)

MODEL 1: Linear Regression - 3-Day Ahead WTI Price
=====

```

```

R2 Score   : 0.9150 (% variance explained)
RMSE        : $2.77 / barrel
MAE         : $1.83 / barrel
Naive MAE   : $8.26 (predict-the-mean baseline)
=====

```

Standardised Coefficients (most influential features first):

feature	coefficient
price	27.002101
ma_20	2.205627
ma_50	1.778572
volatility_20d	0.973972
vol_zscore	-0.908928
ma_gap	0.551335
momentum_5d	0.537903
era_num	0.221434
return_1d	-0.133650
price_to_ma20	-0.130467
near_event	0.038891
rsi_signal	0.008048

Interpretation: Model 1 Results Current-run signal quality: - R^2 0.915, MAE \$1.83 versus naive baseline MAE \$8.26. - This indicates strong short-horizon level-tracking under the current feature set and sample construction.

Coefficient reading for decisions (not causality): - Price and moving-average structure dominate explanatory power, while regime/context features provide secondary adjustments. - Model should be treated as a **risk-aware baseline forecaster**, not a structural causal model.

How target users can use it: 1. **Trading Desks:** convert predicted 3-day level deviation into directional conviction tiers. 2. **Portfolio Managers:** use forecast error scale (MAE/RMSE) as a confidence band for exposure sizing. 3. **Corporate Hedgers:** use the projected 3-day level range to stage hedge entries rather than execute all-at-once.

2.15.3 Model 2: Logistic Regression — 3-Day Bullish Move Classification

The logistic model predicts whether WTI will rise by **more than 0.8% over the next 3 trading days** ($\text{price_up_3d} = 1$).

This reframing reduces next-day noise and makes the classification objective more economically interpretable for tactical positioning. We evaluate both **ROC-AUC** (ranking skill) and confusion-matrix metrics (decision performance at threshold = 0.48 (chosen for better precision-recall balance)).

```
[44]: # Model 2: Logistic Regression (3-day bullish move)
model2 = LogisticRegression(max_iter=3000, C=0.3, solver='lbfgs',
                             class_weight='balanced', random_state=42)
model2.fit(Xc_train_sc, yc_train)
y_pred2_proba = model2.predict_proba(Xc_test_sc)[: , 1]

# A slightly lower threshold improves balance between precision and recall
prob_threshold = 0.48
y_pred2 = (y_pred2_proba >= prob_threshold).astype(int)

acc = accuracy_score(yc_test, y_pred2)
prec = precision_score(yc_test, y_pred2, zero_division=0)
```

```

=== Part 4 Complete ===

SQLite connection closed.

map / apply: era_label, era_num, vol_regime, near_event, rsi_signal, vol_zscore

SQL: 12 queries (3 JOINS, 2 window functions, 5 GROUP BYs, 2 subqueries)

Models: Linear Regression (3-day price) + Logistic Regression (3-day up-move)

Interpretation: Model 2 Results Current-run classification quality: - Accuracy 0.620 vs naive baseline 0.600, ROC-AUC 0.630. - This is moderate but meaningful ranking ability for a noisy short-horizon directional task.

Decision-threshold implication (0.48): - The selected threshold balances false positives vs missed up-moves for tactical usage. - Confusion-matrix trade-offs should be mapped to desk objective (capture upside vs avoid whipsaw).

How target users can use it: 1. **Trading Desks:** use predicted probability as a signal tier (e.g., high-conviction only above internal cutoff). 2. **Portfolio Managers:** treat probabilities as regime indicators for incremental beta tilts, not binary all-in switches. 3. **Corporate Hedgers:** use higher P(up) windows to accelerate buy-side hedging decisions when exposure is short fuel/input costs.

2.16 Conclusions

2.16.1 Summary of Findings

Data quality checks in Part 4 confirm stable date coverage, controlled duplicates, and explicit outlier handling before SQL and modeling.

Research Question 1: How predictable are WTI prices? With a more realistic short-horizon target, the **Linear Regression model** predicting the **3-day ahead WTI price** still performs strongly (high explained variance and low error vs. baseline), confirming that trend and regime features retain useful predictive structure beyond pure noise.

Research Question 2: Has US energy independence reduced the geopolitical risk premium? Yes, structurally. The event study (Part 3) and SQL Q3-Q4 still show that peak crisis responses are materially smaller in the US Dominant era than in the US Dependent era, consistent with a compressed geopolitical risk premium.

Research Question 3: Do participant groups position differently around events? CFTC-based analysis (Part 2, SQL Q7-Q8) continues to show divergence between **managed money** and **commercial hedgers** around major events, supporting the interpretation that positioning extremes can act as contrarian context signals.

Research Question 4: Do technical features add predictive power? After reframing the classification task to a **3-day strong-move signal** ($> +0.8\%$), the **Logistic Regression model** achieves a ROC-AUC clearly above 0.50, indicating non-random directional ranking ability. At the tuned 0.48 decision threshold used in this notebook, precision-recall trade-offs remain meaningful, suggesting signal exists but should be calibrated to each desk's objective (capture rate vs. false positives).

2.16.2 If More Time: Additional Datasets

To further strengthen the same core storyline, the next datasets to add would be: 1. **EIA weekly crude inventories** (supply shock context around event windows). 2. **WTI term-structure features** (front vs next contract spread / roll-yield proxy). 3. **Oil options implied volatility (e.g., OVX)** to compare realized-vs-implied risk conditions.

These additions would mainly improve risk calibration and out-of-sample stability checks for the same audience use-cases.
